**A study of the aftershock sequence of the Tohoku, March
2011 (M=9.0) mainshock**

DIPLOMA THESIS

Thessaloniki, 2014

ABSTRACT

Japan has a long and interesting geologic history, since it is situated on the boundaries of major tectonic plates, continuously forming an arc system since the Permian due to subduction of the Pacific Ocean floor. The active margin of the floor is the cause of earthquakes that form a subducting zone, as it has been discovered by the great seismologist K. Wadati, extending to depths of 500 km.

The purpose of this project is the understanding of the tectonic evolution of the Japanese arc system through studying the evolution of aftershock sequences. During the last decades, efforts have been made towards predicting where or when a large aftershock will occur since a seismic excitation has started. Most interesting results came from studying seismic sequences and more specifically from their time distribution, spatial distribution, time – space distribution and magnitude distribution.

In this research a procedure is applied for estimating the strongest earthquake of a seismic sequence, taking published knowledge into consideration and new experience on time, space, time-space and magnitude distribution of non-strong earthquakes of a seismic sequence.

Data used concern a time interval of 10 years, from 2000 to 2010 in the Tohoku region that consists of the northeastern portion of Honshu, the largest island of Japan. In this region faults and volcanoes are considerably active in the last 10.000 years. Most earthquakes occur at depths less than 15 km (Zhao et al., 2000) and less frequently they occur beneath the land.

This research was conducted in an attempt to understand how seismic sequences evolve, through main shock, foreshock and aftershock sequences and hoping in a better short-term and long-term prognosis of earthquakes.

Chapter 1

1.1 Concepts and Definitions

1.1.1 Seismic Sequence

Frequency and maximum magnitude of earthquakes are not stable but they vary with time. These changes can happen either on the fault or at the area closest to it, as in time-changes of the seismic action that is related to the seismic circle and seismic sequences.

Seismic Cycle is the repetitive procedure of accumulating and releasing elastic deformation (strain energy) at the fault triggered when an earthquake takes place. The period of the repetition is the duration of the seismic cycle (Fedotov, 1968).

Seismic Sequence is the series of earthquakes with varying magnitudes that occur at a place usually within a small interval of a few days or a few weeks. During that interval, the frequency of the earthquakes is high. The biggest earthquake is called **main shock**, whilst the earthquakes that precede and follow the main shock are called **foreshocks** and **aftershocks** respectively.

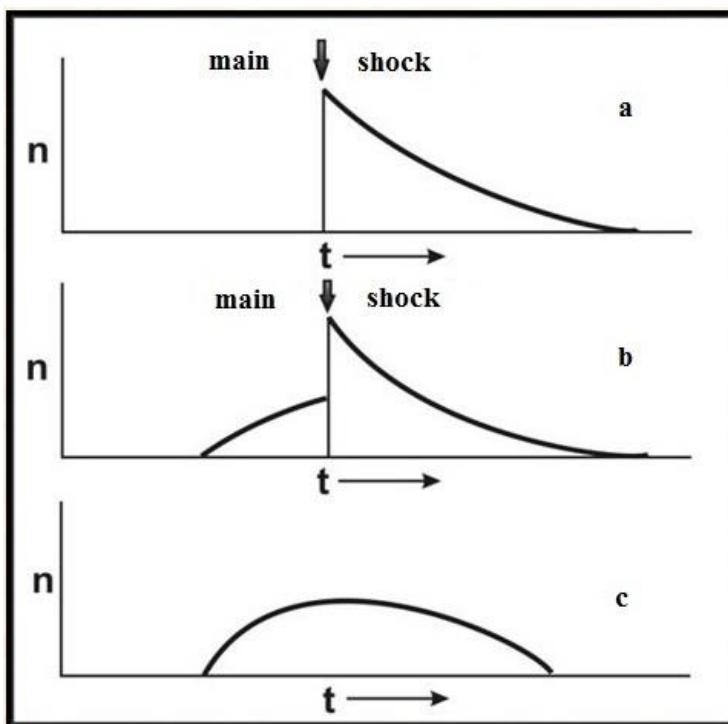

Figure 1: Different kinds of seismic sequences.

Figure (1) illustrates the three basic categories in which seismic sequences can be divided.

- * In the first case, the main shock has occurred without being preceded by foreshocks but being followed by aftershocks whose frequency is reduced with time (Figure 1a).
- * In the second case, the main shock is preceded by foreshocks and followed by aftershocks (Figure 1b).
- * In the cases where there is not an earthquake in a sequence that has greater magnitude than all the rest, then we have earthquake swarms (Figure 1c). Initially, the frequency of these earthquakes increases continuously until it reaches its maximum value and then it decreases in order to acquire its usual form once again. They occur usually in volcanic areas and they are generally small earthquakes.

1.1.2 Laws related to seismic sequences

- According to **Båth**'s law, the difference between the magnitude M_0 of the main shock and the magnitude M_1 of the largest aftershock is, on average, equal to 1.1 – 1.2, regardless of the magnitude of the main shock (Båth, 1968; Papazachos 1974, etc.). So it is: **$M_0 - M_1 = 1.1$** .

It appears that, this variation (Δm), does not depend only on the distribution of the magnitude of the earthquakes but also on the aftershock sequence. A big difference in Δm can be due to a small magnitude aftershock activity. Basically, the origin of Bath's law is to be found in the selection procedure used to define mainshocks and aftershocks rather than in any difference in the mechanisms controlling the magnitude of the mainshock and its aftershocks (Hlemstetter and Sornette, 2003).

- The frequency, n , of aftershocks or rather, the number of aftershocks in a unit of time (e.g. a day) follows the **Omori** law or its modified form (Omori 1894, Utsu 1961). It is an empirical formula that provides an appropriate representation of the temporal variation of aftershock activity measured after the main shock occurs: $[n(t)=K/(t+c)]$ and the modified form: $[n=n_0 \cdot t^{-p}]$, where k, c , are parameters calculated from the available data, p corresponds to the decay rate and typically ranges from 0.7 to 1.5 and n is the frequency of the earthquakes.

Parameter c has small value (≈ 0.03) and parameter k is a measurement value for the aftershock activity since it corresponds to the frequency of the earthquakes one unit of time after the occurrence of the main shock.

According to these equations, the rate of aftershocks decreases quickly with time. Whatever the probability of an aftershock is on the first day, the second day will have 1/2 the probability of the first day and the tenth day will have approximately 1/10 the probability of the first day (when p is equal to 1).

- The distribution of the magnitudes of aftershocks, foreshocks and swarm earthquakes follows the statistical **Gutenberg - Richter** law (Gutenberg and Richter, 1944) described by the formula: $\log N = a_t - bM$, where:

N is the number of earthquakes that occur at a certain place, a_t is a parameter that depends on the seismicity of the place, the area of the surface that is covered by the epicenters (aftershock zone) and the time interval. In seismicity studies we usually use the reduced value a for one year of this parameter: $a = a_t - \log t$. b is a parameter that depends on the mechanical properties of the material and the dominant stresses. M is the magnitude of the earthquakes.

Therefore, for an interval of 1 year the formula is: $\log N = a - bM$. Parameter b expresses the rate of the increase in the number of earthquakes as their magnitude decreases. Its value ranges from 0.4 – 1.4. It changes as regards depth (as depth increases, b value decreases) and geological age of the place (for Alpine zones ranges from 1.0 – 1.8, whereas in continental platforms from 0.6 – 0.7). It also depends on stresses and mechanical properties near the focal area. When we study swarm earthquakes, parameter b shows great deviation from value 1 (usually 2 to 2.25) while in aftershock sequences has lower values and in the cases of foreshock sequences even lower. This is due to heterogeneity of the material at the rupture zone. Before the main shock some anomalies may be observed with regional stress increase, but the occurrence of the main shock causes new cracks (fractures) from where part of the energy is released in the form of heat, whereas the rest of the energy is released by aftershocks. Therefore, the more heterogeneous the material, the more foreshocks and aftershocks occur (Mogi, 1962). In highly heterogeneous areas, swarm earthquakes are common.

In addition, the way an earthquake is generated is determined by the stress at the focal region. According to experiments (Scholz, 1968) the value of parameter b is small when there is high stress and high when the stress is small.

Parameter **a** expresses the logarithm of the number of earthquakes with magnitude 0 and above and its value depends from:

- The time period of the observations,
- The extent of the area in observation,
- The seismicity of the region.

These parameters can be estimated by the graph of $\log N$ against M, as we can see in the following example:

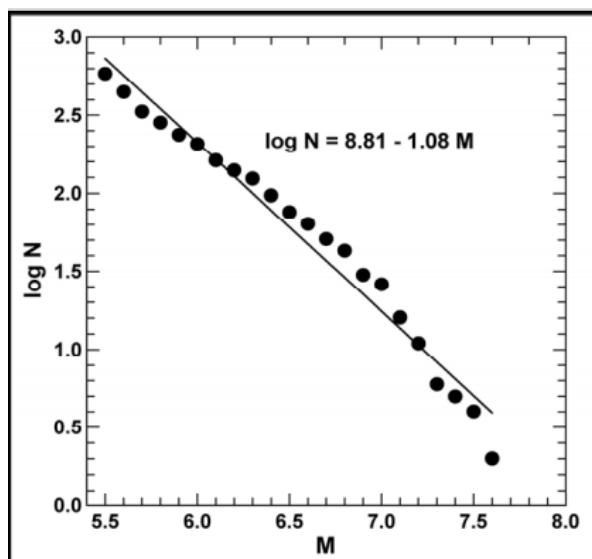

Figure 2: Distribution of the cumulative frequency of the magnitude of earthquakes in Greece regarding the time period between 1901 and 2004 (with data taken from Papazachos et al., 2004 catalogs).

Another method for calculating parameters a and b is based on **Gumbel's theory** (1958) according to which the knowledge of all magnitudes of earthquakes occurring at a certain area during a certain time period is not necessary and the only knowledge needed is that of the magnitude, M_j , of the biggest earthquake happening in each of the equal time spaces that the period is divided in and there are seismological data for it.

1.1.3 The way a seismic sequence is evolved

The procedure of assessing the way a seismic sequence evolves is based on the study of time variation of the frequency, spatial distribution, space – time distribution and magnitude distribution of the small and moderate magnitude earthquakes, in order to predict the stronger earthquakes.

- Time variation is the feature of seismic sequences that is usually observed in shallow shocks and is called *normal evolution* of the sequence, since it concerns the occurrence of a main shock and the aftershock that follow.

The frequency, n , of the aftershocks of such a sequence varies with time:

$$n=n_0 t^h \quad (1)$$

Where t is the time measured from the origin time of the main shock and n_0 and h are parameters calculated from existing data (Mogi, 1962).

The relation above (1) takes the form of $\log n = n_1 - h \log t$, where n_1 and h can be calculated by the least squares' method.

It has already been proved that aftershocks decrease with time from the main shock (Omori, 1894). Therefore, when a deviation from this decrease is observed, then there is a possibility of non-normal evolution of the sequence, which may be related to the probable occurrence of a strong aftershock.

- Spatial distribution of the earthquakes of a sequence determines the rupture zone of the main shock while foreshocks usually are located near the focal region of the main shock. (Papazachos et al., 1983).

Consequently, studying spatial distribution we can observe that foreshocks are located near the epicenter of the main shock, while aftershocks cover the entire fault zone.

- Time – Space distribution of a sequence is important while we can study it in a more general field. Studies have shown that, in the cases where the mainshock occurs in the center of the fault, the aftershock activity migrates to both ends of the fault (**bilateral rupture**). It is possible that near one end of the fault the largest aftershock may occur.

In the cases when the main shock occurs to one end of the fault (**unilateral rupture**), then seismic activity migrates to the other end of the fault, where later the largest aftershock may occur (Karakaisis et al., 1985).

- Finally, magnitude distribution helps also to classify a seismic sequence. For example, when a seismic excitation starts we can calculate the parameter **b** from the formula **log N = a - bM**, and if its value is relatively small (~0.7) then it may correspond to a foreshock sequence, whereas if its value is greater (~1.0), then it's an aftershock sequence and lastly, if its value is even greater, then we expect swarm earthquakes (Papazachos, 1974).

Consequently, with this procedure we can assess the way a seismic sequence evolves. Thus, if we observe a normal evolution of the sequence, then we do not expect another earthquake comparable to the main shock or with greater magnitude, but if the evolution is not normal then another strong earthquake may be expected to occur, which may cause additional damage to structures that have already been affected by the mainshock.

Chapter 2 – Geological framework of Japan

2.1 Tectonic Setting

2.1.1 Introduction

The recent tectonic setting of Japan is a result of the interaction of 5 tectonic plates from Silurian until Pleistocene that lead to Japan's current topography with the four islands: Hokkaido, Honshu, Shikoku and Kyushu (Figure 3b). These plates (Fig. 3a) are: Eurasian (Amour plate), Okhotsk plate, North American plate (whose boundary with Eurasian does not seem to be active, crosses Siberia and passing across the west side of Okhotsk sea, meets Japan), the Pacific plate and Philippine plate (Wei and Seno 1998).

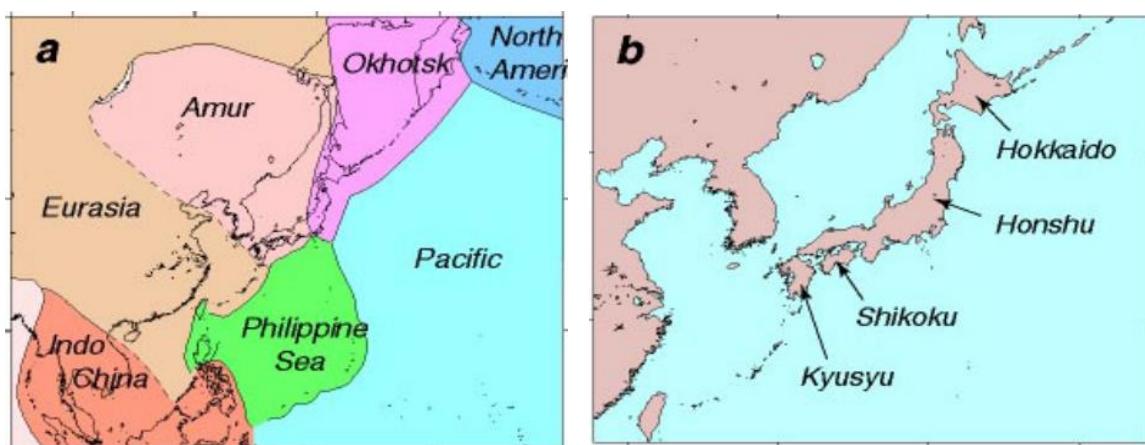

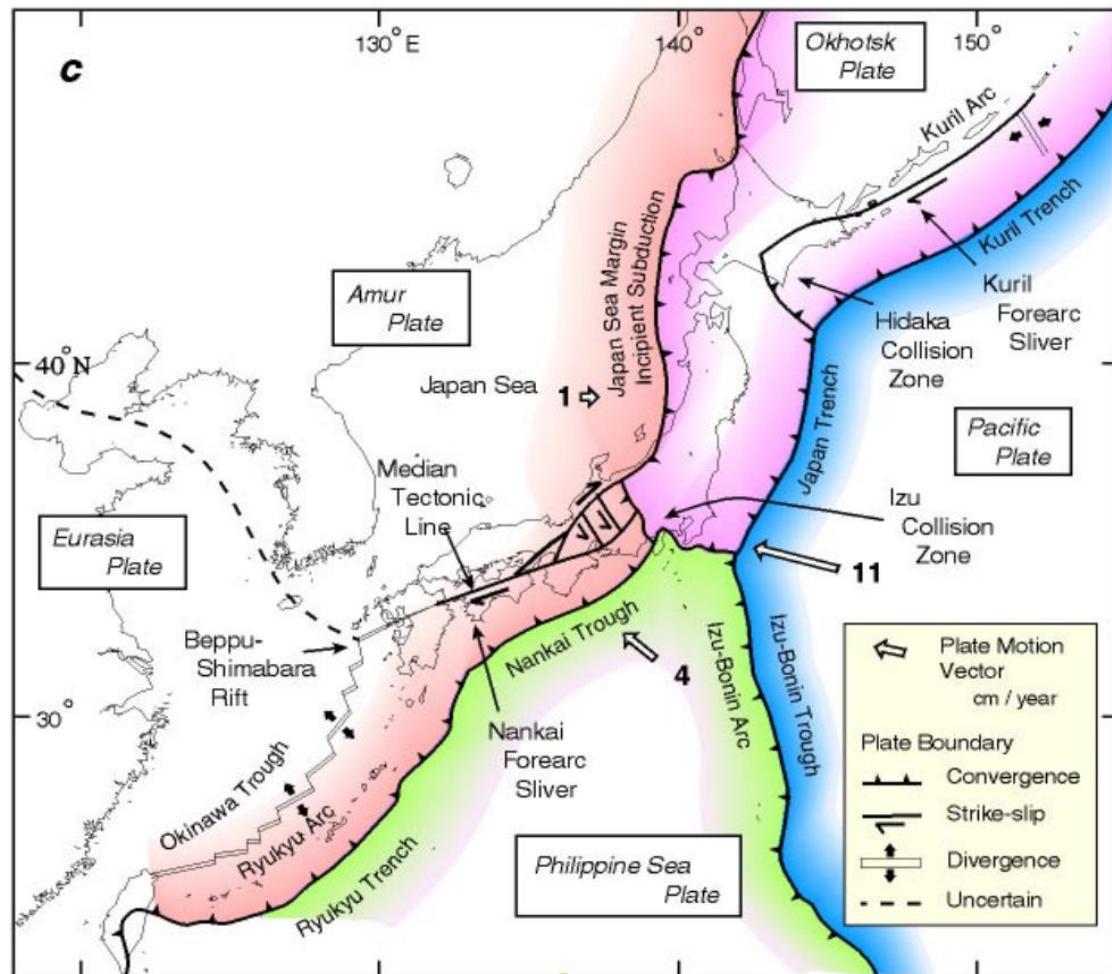

Figure 3. (a) The lithospheric plates in the broader area of Japan (Wei and Seno, 1998), (b) The four major islands that comprise Japan.

Japan is a typical example of an arc – trench system, with the Pacific plate subducting beneath Okhotsk plate and Philippine plate beneath the Eurasian plate. Thus, Japan that was once attached to Asia, began throughout the geological time, to move away due to tensional forces from the subduction and finally was formed as an arc – shaped island arc as we can see in Figure 3b. At the convex side of the arc, deep trenches are formed: Kuril trench, Japan Trench, Izu – Bonin trench, Ryukyu trench and Mariana trench (one of the deepest trenches, with depth exceeding 11000 m).

At the inner concave part, the volcanic arc is formed as the Pacific plate subducts in the hot mantle forming active volcanoes along Japan. If we move further to the interior there is the Japan Sea, that corresponds to the marginal (back – arc) basin of the arc system.

Picture 4 : Boundaries and convergence of the Tectonic plates in the arch system of Japan. In central Honshu the Median Tectonic Line, MTL is dominant with complex microplate tectonics and right – lateral motion (modified by Taira et al 2000).

In more details (Fig. 4), the subduction of the Pacific plate at Kuril arc is oblique. This motion resulted in the formation of a collision zone in central Hokkaido (Hidaka collision zone). The subduction continues at the Japan and Izu – Bonin trenches. In addition, the east – west directed convergence between NE Japan (Okhotsk plate) and Amur plate has set in motion a subduction zone on the eastern margin of the Japan Sea (i.e. Nakamura 1983, Tamaki and Honza 1985).

Moreover, Philippine Sea plate and its northwestward subduction that is oblique to both the Nankai trough and the collision zone between Izu – Bonin island arc and Honshu arc leads to the westward migration of a fore arc sliver (Nankai Forearc Sliver) (Fitch 1972).

The Median Tectonic Line (MTL, Figures 4 and 5) corresponds to the region of the forearc of Japan, where a sedimentary basin is formed. The sediments present a difference in the degree of the metamorphism from the trench to the outer side of the arc, as the cold plate subducts and enters the hotter mantle as we can see in the figures below (from Tectonics and Geological Mapping Lab of National and Kapodistrian University of Athens):

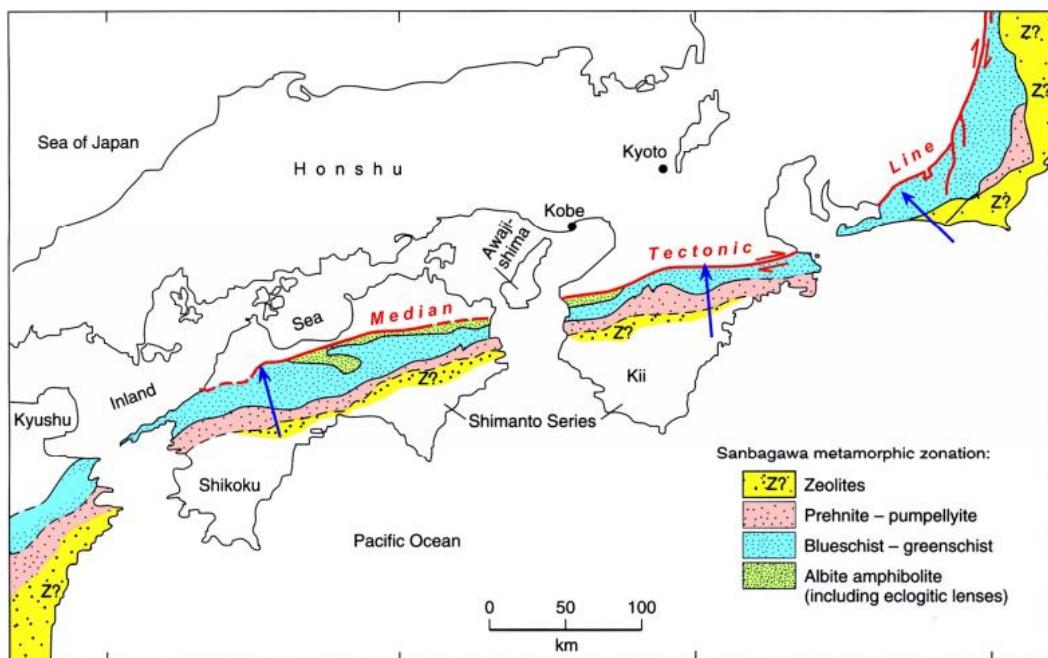

Figure 5. Metamorphosis at subduction zones is characterized by a zoning of progressive increase in the degree of the metamorphosis from the trench towards the outer side of the arch (from zeolite facies, to prehnite – pumpellyite facies and last to Blueschist – greenschist facies).

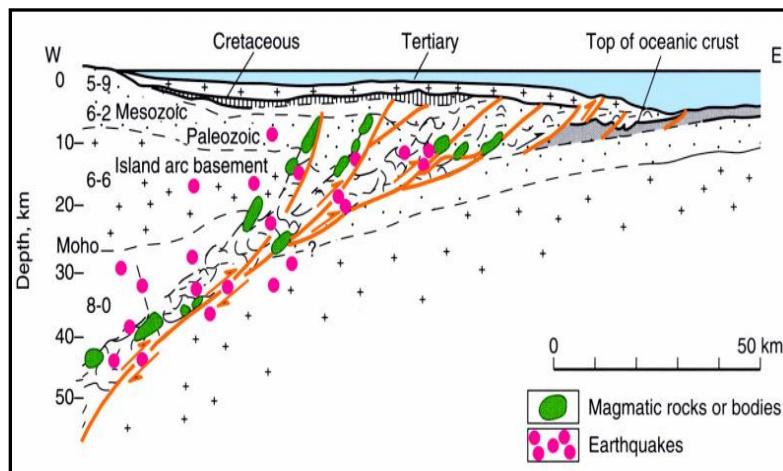

Figure 6. Schematic section of the forearc region of Japan with the Cretaceous and Tertiary sediments, magmatic rocks or bodies and the epicenters of the earthquakes.

Another interesting characteristic of Japan or in general of continental-oceanic convergent plate boundaries is the Wadati – Benioff zone. Figure 6 depicts the significance of shallow and intermediate earthquakes but even the deeper ones ($h > 60\text{km}$). It is observed that the depth of the earthquakes increases as we move from the outer side to the inner side of the arcs with depths of earthquake foci that can exceed 500 km. Thus, the earthquake foci form an amphitheatric surface that inclines towards the inner part of the arc. This zone of depth earthquakes is called **Wadati – Benioff zone**.

To the depth of 60-80 km, the earthquake foci are on the contact surface of the two converging lithospheric plates, while for greater depths (even up to 720 km) the earthquake foci are located on the upper part of the subducting plate. It has been observed that along some subducting plates there are two parallel seismic zones, one near the upper surface and the other a little deeper (Hasegawa et al., 1978).

2.2 Ring of fire

The ring of fire is related to and is a direct result of motion and convergence of the tectonic plates. Is an area that consists of a nearly continuous series of oceanic trenches, volcanic arcs and volcanic belts. It includes 452 volcanoes, 75% of whom are active or dormant. Also, 90% of earthquakes on the earth and about 80% of the biggest earthquakes occur along this ring. The east part (Figure 7) is a result of the motion of Nazca and Cocos plates that subduct under the South America and the Caribbean, respectively, forming the Andes and volcanoes such as Cotopaxi and Azul.

At the west part, the subduction of Pacific and Philippine plates are responsible for the formation of the Japan Islands and volcanoes, such as the most noted mountain Fuji.

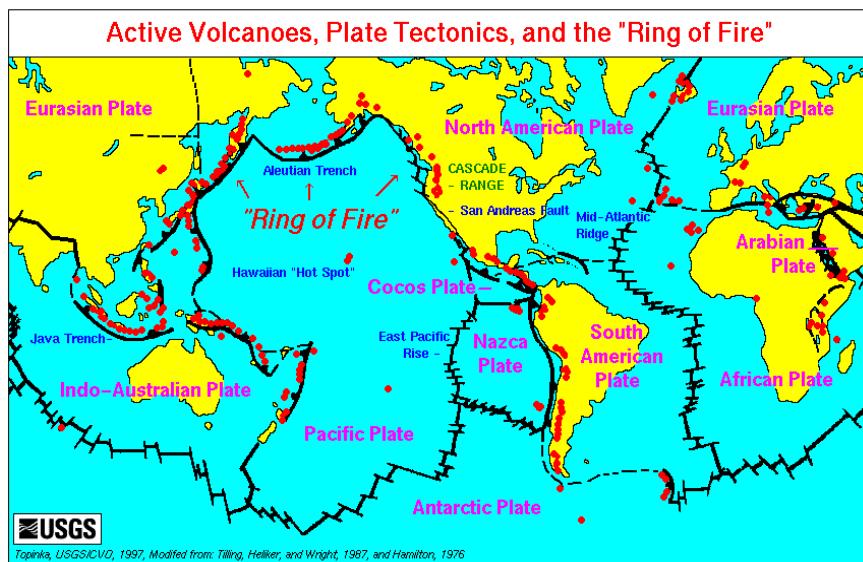

Figure 7. Ring of Fire – Motion of the tectonic plates.

Japan is a part of Eurasia and consists of more than 6.000 islands. Many scientists claim that most of those islands were below sea level before Miocene. In early Miocene, the motion of the Pacific, Philippine and Eurasian plates was followed by volcanic activity resulting in the immersion of many of those islands. At the end of Miocene, the recent islands of Japan were formed with volcanic arcs and trenches.

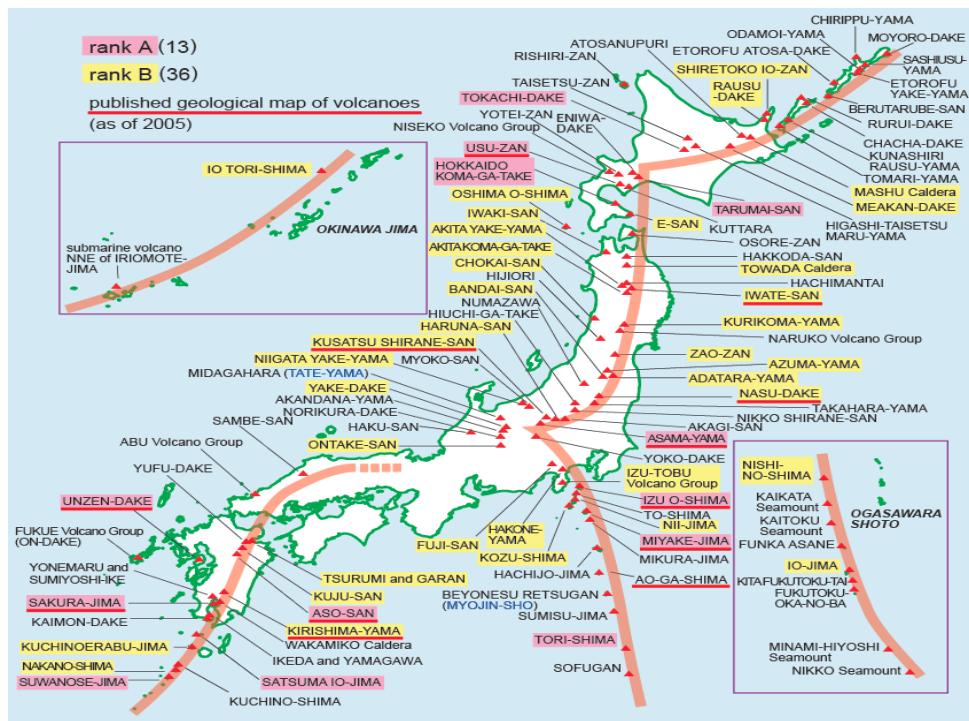

Figure 8. Map showing the volcanoes in Japan.

Most volcanoes are active since Holocene and are mainly stratovolcanoes with lava flows and small pyroclastic flows. These volcanoes are extremely hazardous because their activity is connected to the ring of fire that up until now still continues to move and shift. At the Island of Kyushu there are calderas since Miocene, when they were in abundance and at Beppu - Shimabara basin we can see plateaus since Pleistocene (Kamata and Kodama 1994). This was caused because the NW Japan arc encounters the Ryukyu arc and acquires direction parallel to it (Figure 8).

2.3 Seismicity

As we mentioned earlier, Japan has the characteristics of a subduction zone (oceanic crust beneath continental), thus forming a volcanic arc. This arc system has occasional volcanic activity and frequent moderate and large seismic activity, while situated on the intersection of major tectonic plates (Figure 9).

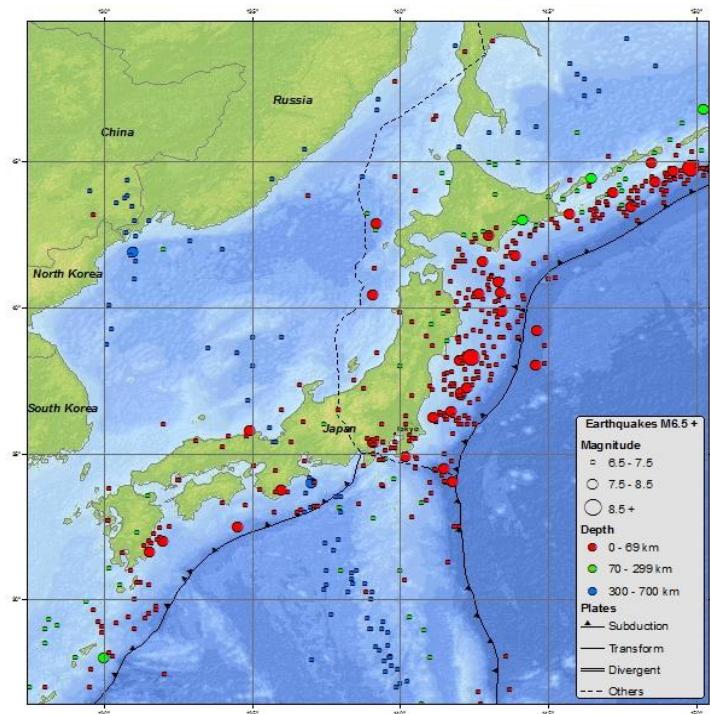

Figure 9. Map of seismicity for M6.5 earthquakes or above, showing also the depths of their foci and the main tectonic features (1900 – March 2012) (USGS).

2.3.1 Major Tectonic Zones

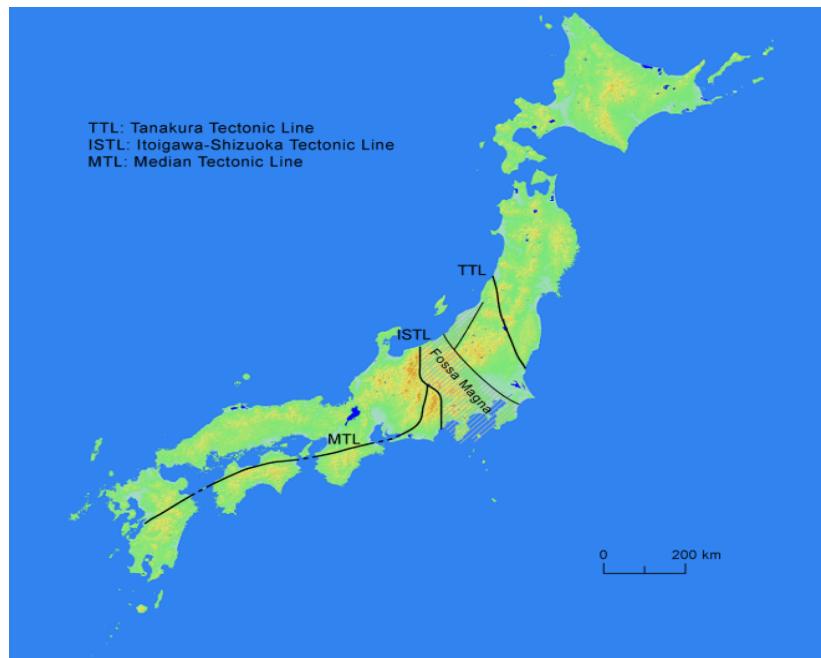

Figure 10. Map of major Tectonic Zones in Japan (GLGArcts).

The major tectonic features in the study area, are:

- **MTL** or Median Tectonic Line, is the longest tectonic line in Japan with length approximately 1.000 km from east to west (from east Kyushu to Central Honshu). Before Miocene its motion was left – lateral, but the recent faults of this zone are of right – lateral motion (Tabei et al., 2002).
- **ISTL** or Itoigawa – Shizuoka Tectonic line, is the line that separates the Japanese island arc to Northern and Southern arc. It is an almost E-W compression zone and can be explained not only by the subduction of Pacific and Philippine plates, but also by a slight east – ward motion of the Eurasian / Amour plate (Wei and Seno, 1998).
- **TTL** or Tanakura Tectonic Line, is a rupture zone formed by strike – slip faults in South Tohoku. It is associated with the North American / Okhotsk plates and Eurasian / Amour plates, whose boundaries, with recent interpretations, extend from Sakhalin island, through the East side of Japan Sea until the Itoigawa – Shizuoka Line (Nakamura, 1983; Seno and Yamanaka, 1996).

2.3.2 Active faults

The last 30 years efforts have been made to map the active faults in Japan (faults showing signs of motion in Quaternary) through topographic analysis and trench excavations. The collection of maps was published by Research Group of Active Faults in Japan (1991) and more recently a portion was presented by Tokuyama et al (1999). The most important findings of the research are reviewed to:

- In Hokkaido, a significant fault system is present along the western foothills of the Hidaka Mountains. This system is part of the foreland thrust belt of the Hidaka collision zone.
- In Western Hokkaido and NE Honshu there is a N – S trending reverse fault system that indicates an E – W compression.
- Central to NE Honshu is dominated by a dense system of strike – slip faults with a direction of NW – SE and NE – SW.

South, these systems are bounded by the Median Tectonic Line (MTL) and can be explained by an E – W compressional stress (Kanaori et al, 1992; Kanaori and Kawakami, 1996).

- In the vicinity of Izu collision zone, the fault system is related to the configuration of the plate boundary (Huchon and Kitazato, 1984).
- In Central Kyushu the westward extension of the Median Tectonic Line connects with a N – S extension zone, which continues to the eastern end of the Okinawa trough (Okamura et al., 1992).

2.4 Crustal Deformation inferred from GPS Geodesy

More than 1000 GPS stations are distributed throughout the Japanese arc with an average spacing of 25-30 Km, constituting one of the densest GPS systems in the world (Abe and Tsuji, 1994; Miyazaki et al., 1997). This GEONET network, is maintained by the Geographical Survey Institute of Japan and provides a detailed image of the deformation of the crust, as it is shown in Figure 11 with the velocity vectors. The data indicate how plate tectonics relates to crustal deformation in an island arc system (Kato et al., 1998; Le Pichon et al., 1998; Sagiya et al., 2000).

The main observations are summarized below:

- From the Pacific side of Hokkaido to NE Honshu, the velocity data (relative to Eurasian plate) show velocities ranging between 3 and 5 cm year⁻¹. This motion represents the elastic strain caused by the westward subduction of the Pacific plate.
- The Pacific side of SW of Japan is characterized by W – NW movement with velocities ranging from 2 to 3 cm year⁻¹. This motion is due to the subduction of the Philippine plate.
- From Southern Kyushu to the Ryukyu arc, data show that the motion is mostly towards southeast, in contrast to the rest of the Pacific side of the arc system. This movement may represent the backarc basin rifting of the Okinawa trough (from the subduction of the Philippine plate under the Eurasian).

- The Japan Sea side of the Honshu arc, including the northern side of the MTL, shows small but constant movement towards the east with the velocity components ranging from a few micrometers to 1 cm year^{-1} . This area belongs to Amour plate. Initially, the existence of this plate was proposed by Zonenshain and Savostin (1981) and its tectonic significance was demonstrated later by Wei and Seno (1998) and Heki et al. (2000).
- The change in the GPS velocity can be explained by examining the strain field. The principal strain axes and shear strain provide further insight.

A zone of high shear strain along the MTL, the northern part of central Japan, and the Japan Sea side of NE Honshu probably marks the principal zone of deformation. This zone has been interpreted as the currently active boundary of the Amour plate and the Pacific side of the Honshu arc (Taira et al. 2000). Therefore, Amour plate plays an important role in intra – arc crustal deformation, which is dominated by east – west compressional stress.

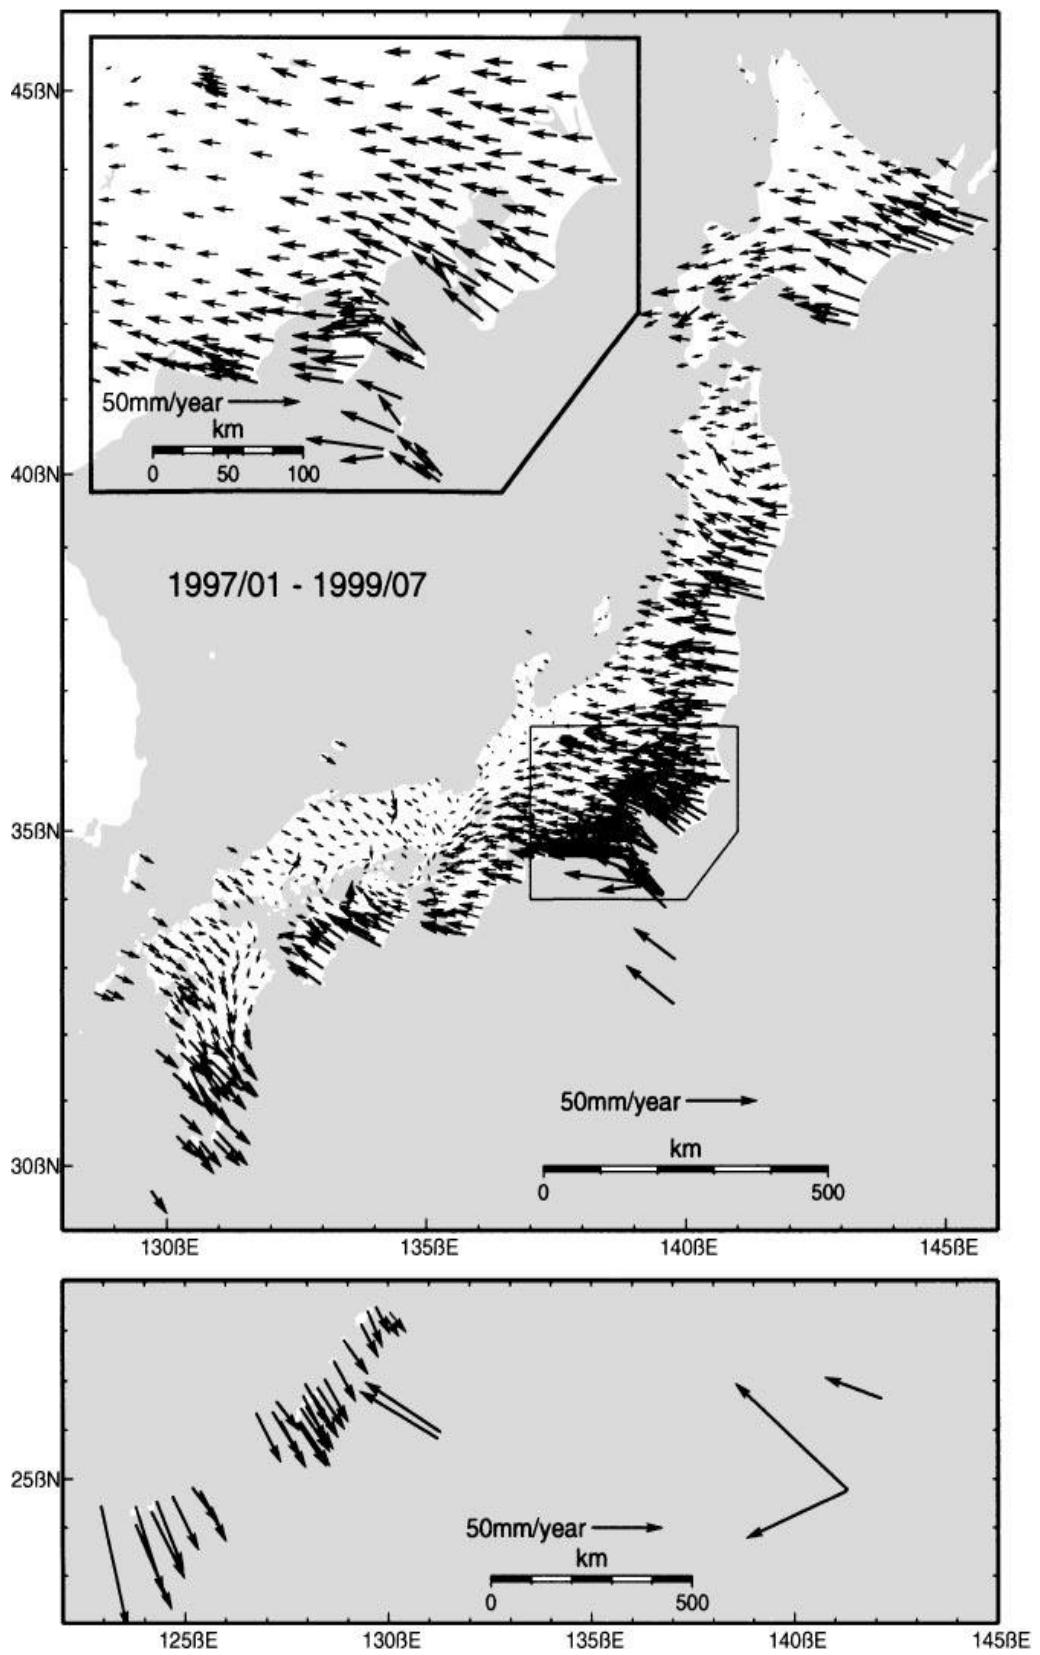

Figure 11. Velocity vectors showing the crustal deformation in the Japan arc system (after Sagiya et al. 2000).

2.5 Surface Geology

The geologic history of the Japan arc is the longest in the west. The oldest rocks are Cambrian and Ordovician ophiolites and associated deep – water sedimentary rocks, which may have been originated in the breakup of the Proterozoic supercontinent (Maruyama, 1997). The majority of the basement rocks, however, consist of younger Jurassic to Paleogene accretionary prisms that precede the formation of the Japan Sea in the middle Miocene (Taira et al. 1989).

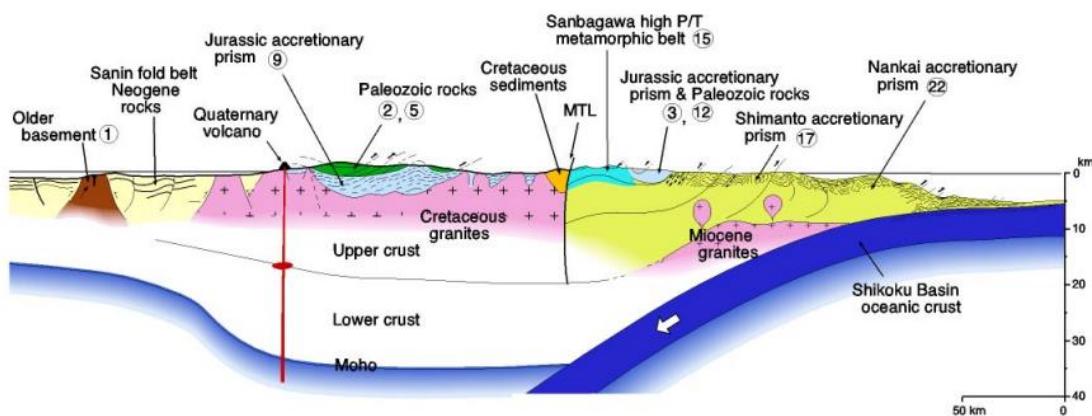

Figure 12. Geological cross section of SW Japan from the Nankai trough to Japan Sea (after Taira et al. 1989 and Maruyama, 1997).

Since the middle Miocene, arc magmatism was the dominant process (Yamaji and Yoshida, 1998; Sato, 1994). In Quaternary, today's tectonic scheme and the modern topography was formed. Two fold – thrust belts were developed at the margin of the Japan Sea after the late Miocene: the Sanin fold-thrust belt in SW Japan (Itoh and Nagasaki, 1996) and the Japan Sea margin of northern Japan (Nakamura 1983) (Figure 12). Tokuyama et al. (1999) discovered that the development of thrusts that involve oceanic basement in the fold-thrust belt of the Japan Sea margin provides a mechanism for ophiolite emplacement.

The geology of the arc can be classified in 5 categories (Taira et al., 1983; Isozaki, 1996):

- Pre – Jurassic units, including Paleozoic ophiolites, sedimentary rocks, metamorphic rocks and granitic rocks.
- Permian to Jurassic accretionary prisms, including high – pressure / temperature (P/T) metamorphic rocks and cover sequences.

- Cretaceous to Tertiary accretionary prisms and cover sequences.
- Neogene and Quaternary igneous and sedimentary rocks.

2.6 Tohoku Region

Tohoku region covers the northeastern portion of Honshu, the largest island of Japan. It is where the Pacific plate is subducting under the plate beneath northern Honshu. The Pacific plate moves at a rate of 8 to 9 cm per year. This motion pushes the upper plate until the accumulated stress causes a seismic slip – rupture event.

The 9.0 magnitude megathrust earthquake occurred on 11 March 2011 in the North – western Pacific Ocean at a relatively shallow depth of about 30 km. An event of this magnitude usually has a rupture length of 500 km and requires a long straight fault surface and because of the fact that the subduction zone in the area of the Honshu rupture is not very straight, this earthquake was a surprise to seismologists.

The main shock was preceded by a number of large foreshocks and followed by hundreds of aftershocks. The first major foreshock was a 7.2 M_w event on 9 March, approximately 40 km from the epicenter of the 11 March event, and other 3 foreshocks on the same day in excess of 6.0 M_w . Following the main event on 11 March, a 6.7 M_w aftershock was reported, succeeded by a 7.6 M_w and a 7.9 M_w events within several hours.

Chapter 3 – Research

I. Introduction

The study of a seismic sequence and the estimation of its evolution during the last decades, has proven to be very essential to predict where or when a major earthquake of the sequence will occur. Still, our observations can't be 100% sure but it helps when it comes to take the appropriate precautions for the area about to get affected.

In order for our prediction to be accurate, we start immediately after the beginning of the seismic excitation (less than one hour, $c \approx 0.03$), we take the measurements from the seismograms, interpret data and calculate the values of the parameters (b , p , etc.) in accordance with time, space and magnitude distribution of the shocks. The procedure is repeated in time intervals that depend on the characteristics of the seismic sequence.

This research is based on catalogs of foreshocks and aftershocks, recorded for the Tohoku region for the 2011 off the Pacific coast of Tohoku earthquake, including date, time of occurrence, latitude, longitude, depth and magnitude (see Appendix).

II. Magnitude distribution

In order for our observations to be accurate we need to determine the magnitude threshold above which no data are missing, i.e. the data are complete. We use the magnitude distribution of earthquakes as described by Gutenberg and Richter (1944) relation:

$$\log N = a - bM$$

The value of the parameter b in this relation characterizes the kind of the seismic sequence, small value for foreshocks, relatively large for aftershocks and even larger for swarms (Papazachos, 1974).

We then plot the logarithm (with base 10) of the cumulative number of aftershocks, figures of $\log N$, against M for a time period of 7, 30 and 100 days after the main

shock (of March 11). Through these plots, with a minimum magnitude of $M_{\min} = 4.1$ and maximum magnitude of $M_{\max} = 7.9$, we find that the completeness magnitude is equal to $M = 4.9$ and the b value is approximately equal to 1.12. Since the completeness magnitude is 4.9, the Least Squares' are applied only on earthquakes of magnitude between 4.9 and 7.9 (the largest aftershock).

The completeness magnitude calculated at this stage, will be used also later in our study.

N , is the number of earthquakes with magnitude equal to and larger than M and a , b are parameters calculated by the observations. Below, we present the plots:

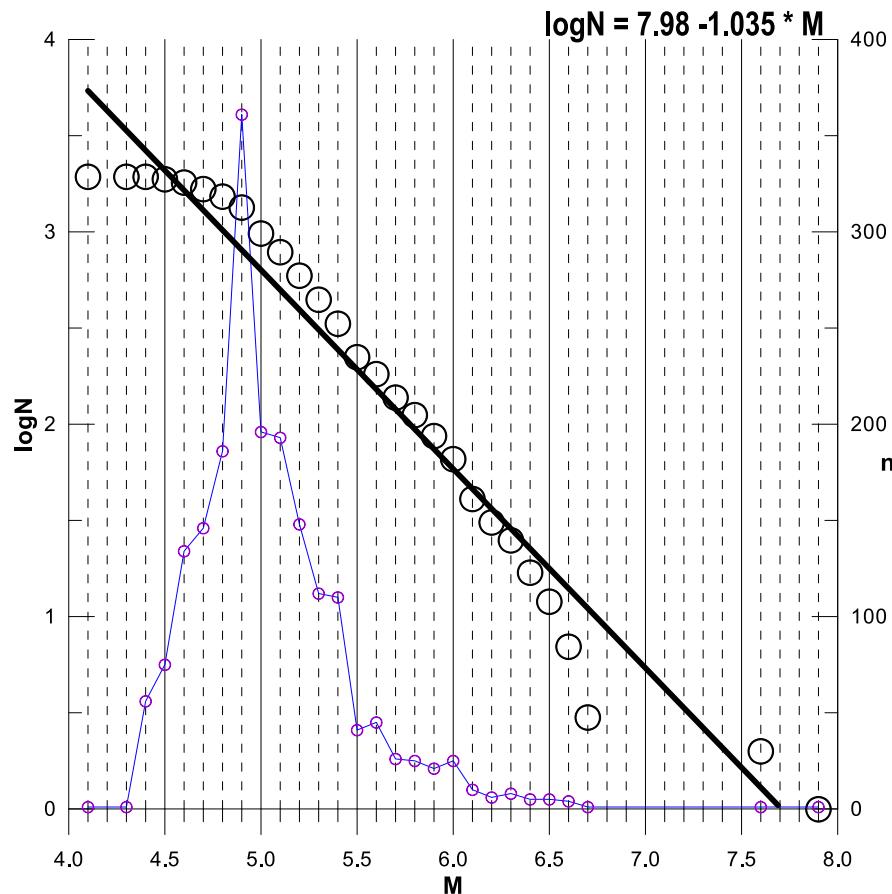

Figure 13a.

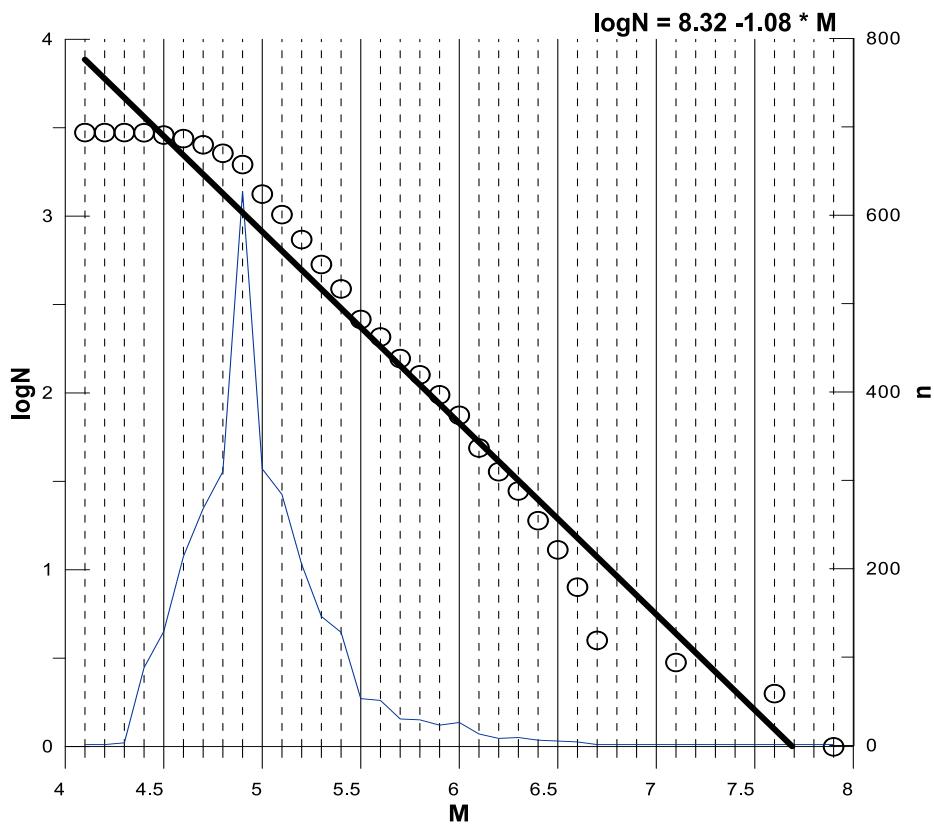

Figure 13b.

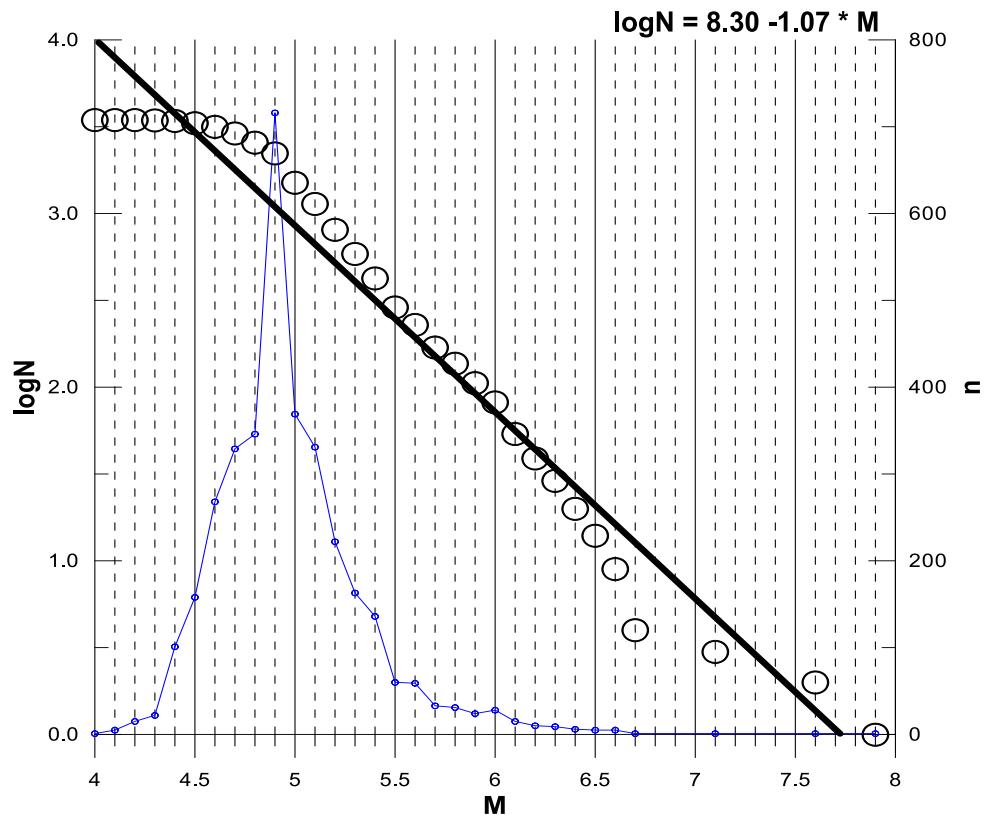

Figure 13c.

Figure 13 shows the variation of the logarithm of the aftershocks against M for a time period of 7 days (13a), 30 days (13b) and 100 days (13c).

We observe that these parameters stay almost constant with a deviation of ± 0.02 which means we expect a normal behavior of the sequence. The parameter b has large value, since it concerns an aftershock sequence.

III. Time Variation

Our next step is to find the time distribution of aftershocks with magnitude larger or equal to the completeness magnitude $M=4.9$ for a time period of 7, 30 and 100 days after the main shock. It is well known that the time distribution of aftershocks follows Omori's law (1894, modified by Utsu, 1961).

To make the following plots we use the relation: $\log n = n_1 - h \log t$, where $n_1 = \log n_0$ and h can be calculated by the least squares' method. The main shock origin time is considered as $t_0 = 0.0$.

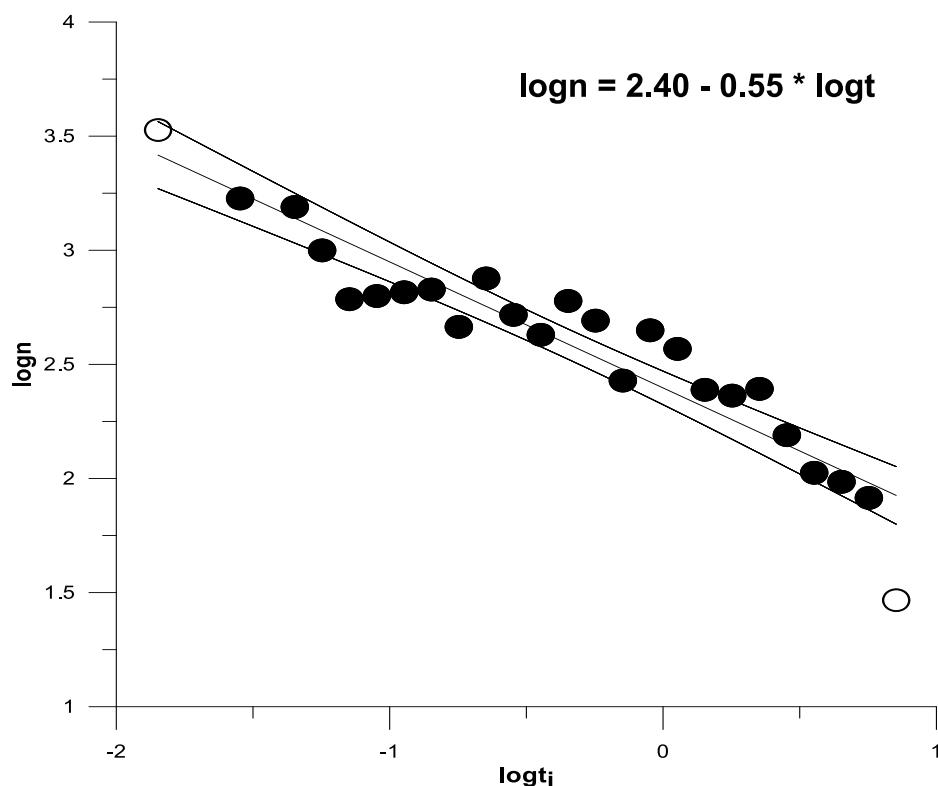

Figure 14a

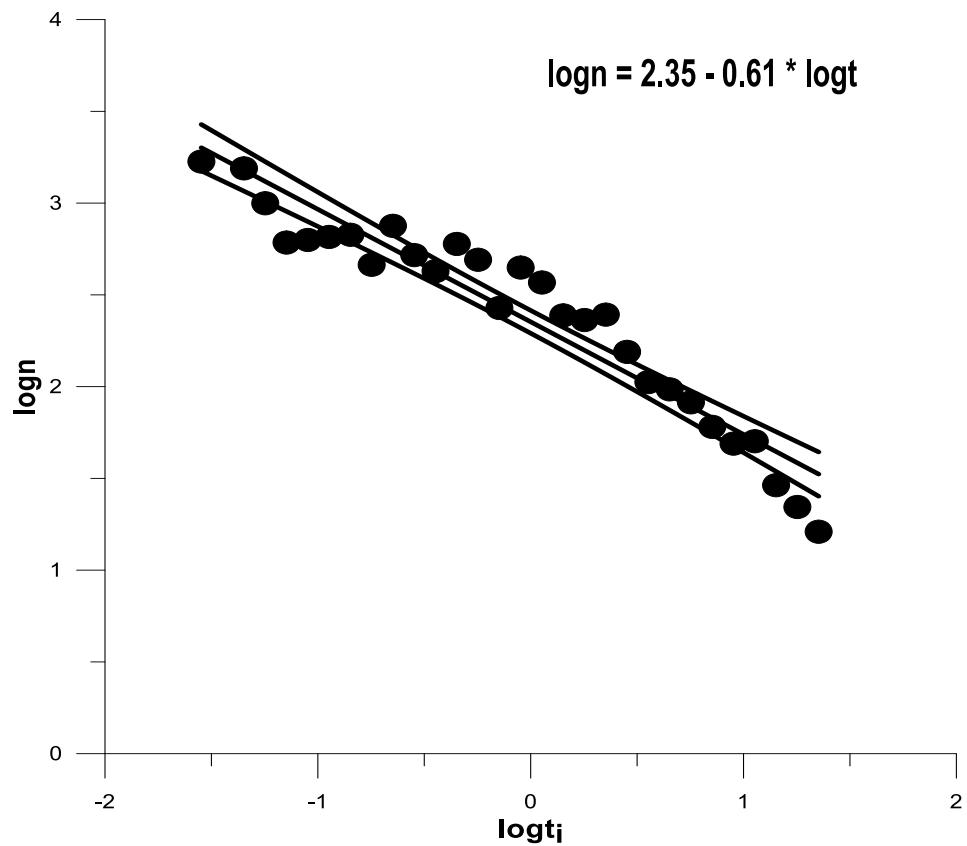

Figure 14b

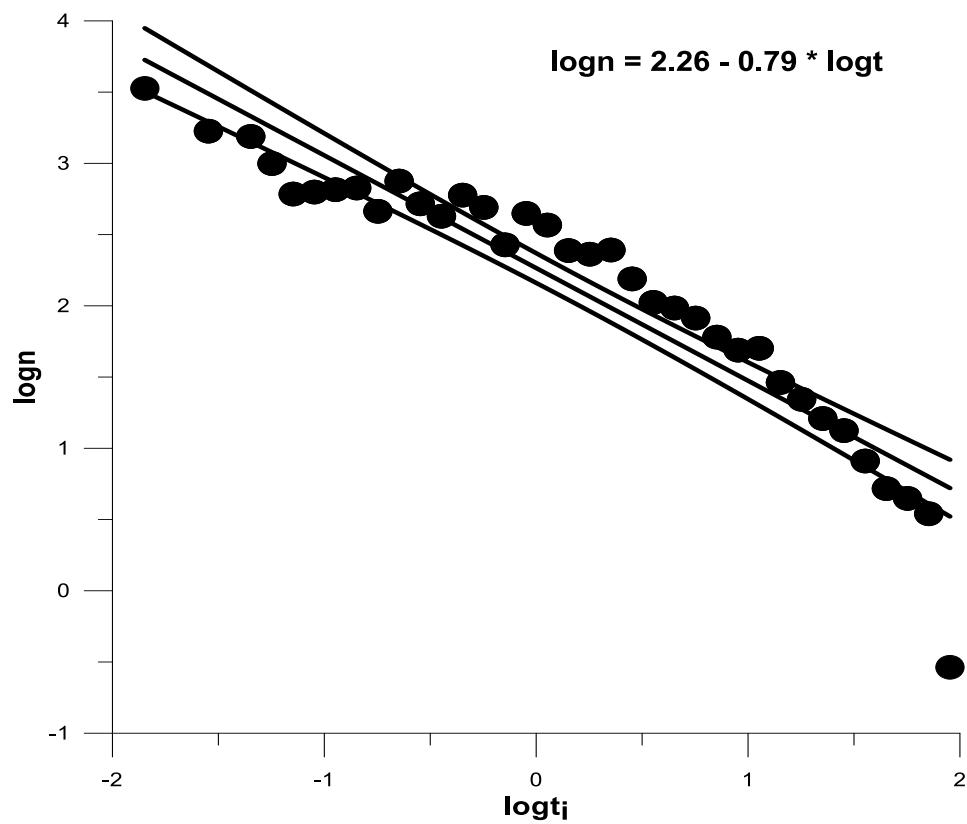

Figure 14c.

Figure 14: shows the time variation of aftershocks within 7 days (14a), 30 days (14b) and 100 days (14c) after the Tohoku earthquake (11.03.2011).

The above figures show the variation of the logarithm of the number of aftershocks of the Tohoku earthquake as a function of the logarithm of time (in days) according to relation (1). The solid straight line in these plots is drawn based on the least squares' method while the other two curved lines define the 95% confidence intervals.

It is noted again that aftershocks decrease with time from the main shock, following a certain law (Omori, 1894). When a deviation from this decrease is observed then the possibility for a non-normal evolution of the seismic sequence is high and the occurrence of a large earthquake is also likely.

In our study the h value is approximately equal to 1 in all three situations (7, 30, 100 days) and is a stable number within the confidence intervals, thus we expect a normal evolution of the seismic sequence.

IV. Time – Space distribution

Since the rupture zone is N – S, we can examine the variation of the latitude of the epicenters of the aftershocks in respect to time after the main shock. Later, we can observe where the seismic activity migrates after the main earthquake, having as goal to predict as much as possible, where the largest aftershock will take place.

Figure 15 below shows the distribution of the epicenters of aftershocks of the seismic fault of the Tohoku earthquake as a function of time.

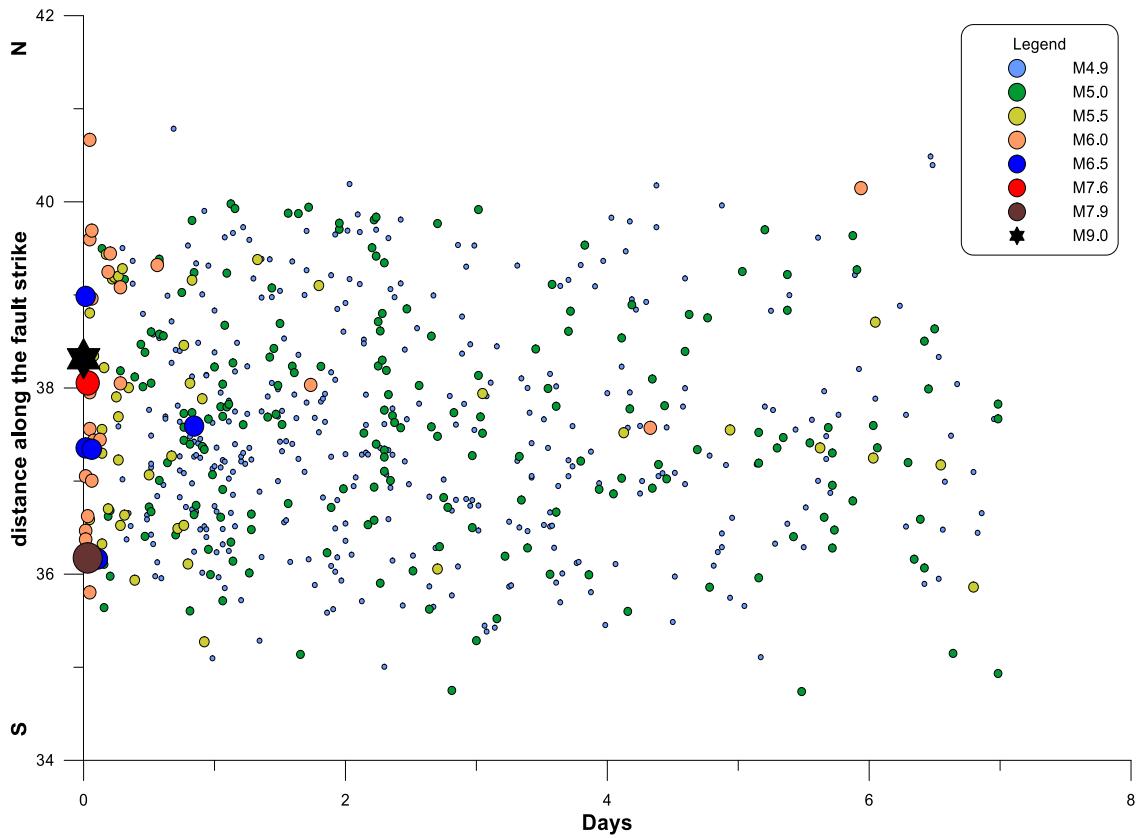

Figure 15: Space – Time distribution of the aftershocks of the Tohoku earthquake. The star shows the main shock of $M = 9.0$ and the colored circles show the aftershocks and their distribution within 8 days.

From Figure 15, we observe that immediately after the generation of the main shock on March 11 from the middle of the fault, the seismic activity migrated more to the south where the largest aftershock occurred after several hours ($M = 7.9$) and where we have the majority of the earthquakes occurring in general.

V. Variation of the mean magnitude and b value with time

At this step we examine the possibility of a change in the mean magnitude and the value of parameter b as a function of time. In order for our results to be comparable, we use a fixed number of earthquakes, for example 100 and a step of 20 shocks.

Below (figure 16), we present the variation of the b-values of these groups of 100 aftershocks as a function of time. The b-value of each group was plotted on the origin time of its last aftershock. The determination of the b-value was based on the classical G-R law as well as on Utsu's relation (1965):

$$b = \frac{\log e}{M_{ave} - M_{min}},$$

where M_{ave} is the mean magnitude of the aftershocks of the group considered and M_{min} is the minimum aftershock magnitude (=4.9).

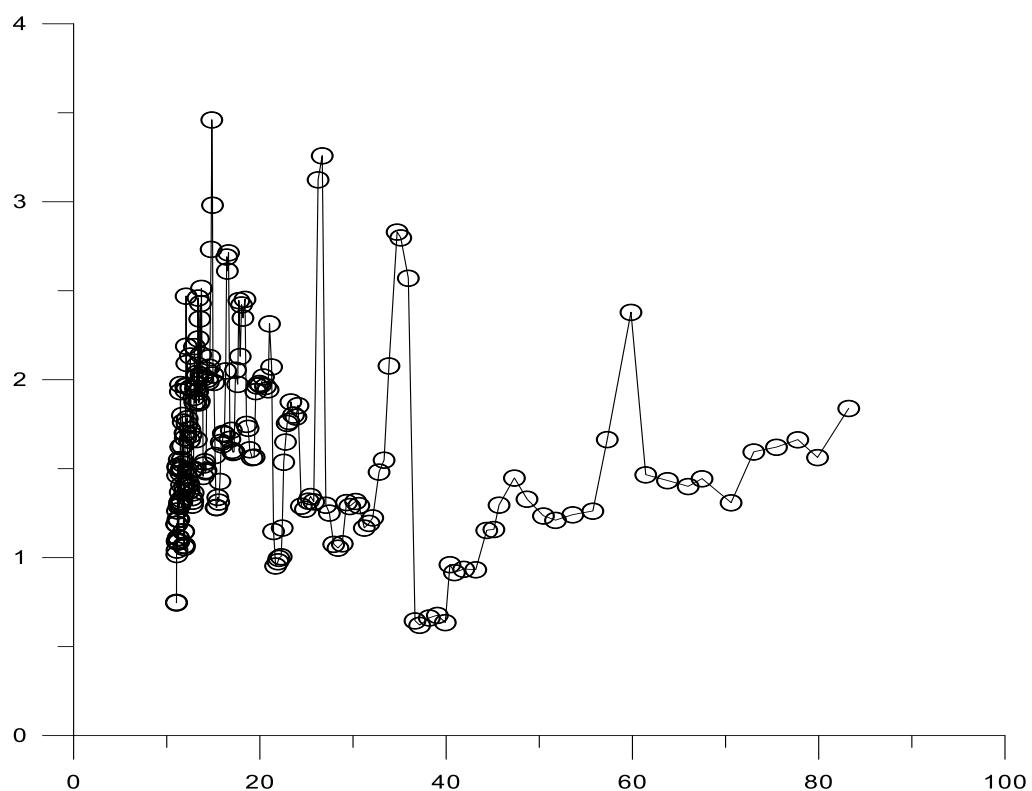

Figure 16a: b-value variation against time (days) based on Gutenberg and Richter.

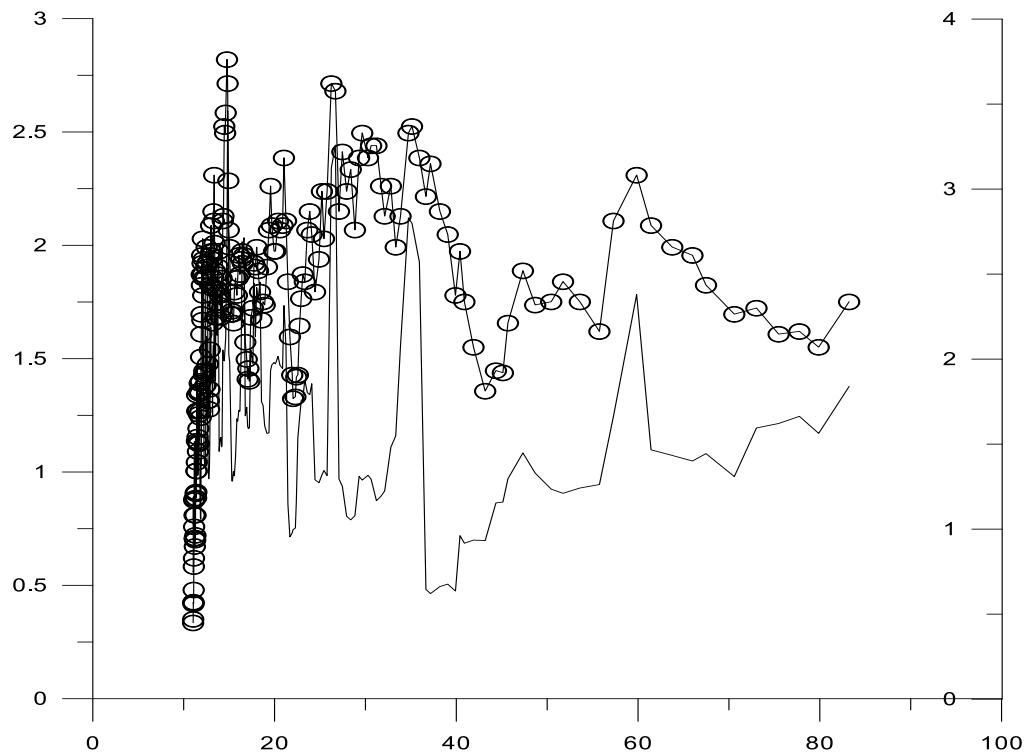

Figure 16b: *b*-value variation against time (days) based on Utsu. The line below the *b*-value distribution derived by Utsu's relation is the same value obtained by the G-R relation (Figure 16a).

This comparison in Figure 16b is presented in order to show that there are no major differences between the two plots and that we cannot see an earthquake that is related to a certain change in the graph, except of course, the M7.9 earthquake.

Conclusions

Japan has the tectonic setting of an island arc where subduction of the Pacific lithospheric plate has been taking place since the Permian. The understanding of the tectonics of Japan's arc system provides useful insight into orogenesis and continental crustal evolution and is the center of many studies and researches. The GPS geodesy, seismicity and active fault distribution of this arc system is one of the best learning objects in the world providing us with knowledge of how the crustal deformation is related to plate tectonics.

Earthquakes in Japan is an everyday phenomenon. Trying to understand how they occur or where and when is something scientists are still figuring out. Studies of the last decades show the significance of seismic sequences in deciphering earthquakes and how they function. These studies deal with time variation, time-space distribution, magnitude distribution and spatial distribution of earthquakes of a seismic sequence (foreshocks, or/and aftershocks). Thus, observations can be made, through data gathered days before and after the mainshock has occurred, and may reveal if the sequence is evolving normally (then we don't expect strong earthquakes but rather much smaller) or if not then we except an earthquake of the same or even larger than those that have already occurred.

In this study we used aftershocks of the Tohoku - Oki megathrust earthquake M9.0 on March 11, 2011. We found the b value to be equal to ~1.12, using the Least Squares Method. The completeness magnitude is found to be equal to M=4.9. Then we use Omori's law (1894) modified by Utsu (1961) and make plots of time variation of the aftershocks. We observe that the seismic sequence evolved in a normal way with parameter h to be equal to ~1. From the time-space distribution we observe that the fault length, where the earthquakes occurred, corresponds to approximately 5 degrees (35 – 40, S – N) and since the arc system we study is a subduction zone we find the fault to have ~500km length, thus the expectation of a large earthquake such as the one on March 11 is very high. Lastly, we examine the b value variation in respect to the time after the mainshock and compare the two results (derived from Gutenberg & Richter and Utsu's relations) to observe that there is not an earthquake relating with certain change except the M7.9, thus we are ensured for the normal continuation of the seismic sequence.

We need to use data such as these (time, time-space, magnitude distribution of foreshocks and aftershocks) as soon as the mainshock occurs to maximize precautions and minimize damage.

Acknowledgements

I take this opportunity to express my profound gratitude and deep regards to my advisor professor Karakasis Georgios of Aristotle University in Thessaloniki, Faculty of science, school of geology. His guidance, monitoring and encouragement throughout the course of this thesis made it possible to broaden my knowledge of Japan's amazing geology in general and form a comprehensive view of seismic sequences and earthquakes.

Thessaloniki, 2014
